State Pattern for both Composite States and specialization of State Machines

BIRGER MØLLER-PEDERSEN, RAGNHILD KOBRO RUNDE, University of Oslo, Norway

Most modelling languages support full state machine modelling, including both composite states and specialization of state machines. Existing approaches to programming with states (state design patterns) either represent composite states by means of subclassing between state classes (and then do not support specialization of state machines), or do not support composite states and instead use subclassing for specialization of state machines. In this paper, we present a state machine design pattern that accomplish both, by using subclassing to support composite states and subclassing to support specialization of state machines.

Categories and Subject Descriptors: D.2.11 [Software Architectures] Patterns; D.2.2 State diagrams

General Terms: Design
Additional Key Words and Phrases: State Machine, Composite State

1. INTRODUCTION

In order to avoid inconsistent model and program artefacts when using both modelling and programming languages during software development, (Madsen and Møller-Pedersen, 2010) proposed the definition of a combined modelling and programming language. The definition of such a language should be based on an analysis of how important modelling concepts can be supported by programming languages. Before embarking upon making new language constructs, it is regarded a good idea to implement the construct in some existing language. This paper describes a state machine design pattern for programming that supports important elements of state machine modelling.

We require all of the most commonly supported mechanisms in modelling languages: composite states (with history, entry and exit actions), and specialization of state machines (all of this supported by e.g. SDL (ITU, 2011) and UML (OMG, 2015)).

As already introduced in 1987 (Harel 1987) a composite state is a state with interior states (contained states) such that all events and corresponding transitions that apply to the composite state by default apply to all of the sub states, unless specified differently. The original state design pattern (Gamma et al., 1995) represent states as subclasses of a general class State, redefining the event methods of State in the different state subclasses. This readily supports simple states. A composite state is usually accomplished by making subclasses (representing the interior sub states) of the class representing the composite state. The event methods of the composite state class are therefore inherited, and event methods may be overridden for the subclass states where the default behaviour specified for the composite state shall not apply.

In 2008, (Chin and Millstein, 2008) demonstrated the need for specialization of state machines (by adding states and events methods, and by extending states), and how to do that by means of a state design pattern. However, using subclassing for specialization implies that this pattern does not support composite states. In order to support both composite states and specialization of state machines we therefore pursue the idea of representing composite states by interior state objects each having a link to the state object for the composite state. Subclassing may then be used for specialization of state machines. With the link from a sub state object to the composite state object, an event method call on a sub state that does not define this event method will be forwarded to the composite state.

2. MOTIVATIONAL EXAMPLE

Figure 1 is the simple state machine of a media switch. It specifies that the initial state of the media switch will be Off (indicated by the black dot with arrow). When powered on it will enter the state On with its initial state CD. The mode is changed by the mode event. The state On has an entry action that is executed whenever On is entered; turning on the display backlight, and an exit action that is executed whenever On is exited, turning off the backlight.

Figure 1 State Machine of a Media Switch

2.1 Composite States

State On is a composite state. The main property of a composite state is that transitions defined for the composite state apply to its contained states, if not specified otherwise. For the MediaSwitch state machine this means that the event off will make the machine enter the state Off, from any of the states in On. The entry/exit actions defined for On do not apply to the contained states; they may have their own entry/exit actions. However, exiting e.g. CD with the transition to off will include the execution of an eventual exit action of CD followed by execution of the exit action of On. Using the state design pattern the sub states CD and TV would be represented by subclasses of the class representing the composite state On. The subclasses for CD and TV would inherit the event method for off from the class representing On, with the possibility to override it. In addition, the subclasses would implement suitable event methods for mode.

2.2 Specialization of State Machines

Recently, (Chin and Millstein, 2008) demonstrated the need for specialization of state machines (called extensible state machines) and how to support that by a design pattern. This is achieved by not using subclassing to specify composite states, but rather use subclassing for extension. The implication is that their state pattern only covers state machines with simple states and not composite states (as these are usually covered by subclassing).

This notion of specialization of state machines is illustrated by defining the MediaSwitch state machine as a specialization of a simpler and more general Switch state machine, see Figure 2.

Figure 2 MediaSwitch as a specialization of Switch
With the extensible state machine design pattern, state classes are defined as inner classes to a state machine class. A specialization is specified by defining a subclass of the enclosing state machine class. In this case, MediaSwitch would then be represented as a subclass of the class representing Switch. Extending a state (e.g. in order to handle additional events or to have inner states) is done by making a subclass of the state class from the super state machine class. This is illustrated in Figure 2 with the On state class, as this is extended to become a composite state and to handle the new event mode. The class for On in MediaSwitch would then be a subclass of the class for On in Switch.

2.3 Problem
There are two problems with the common practice of using subclassing to cover composite states. First of all, subclassing is the obvious mechanism to use for covering specialization of state machines as described above. Composite states must then be supported by another mechanism in order to be able to distinguish between the two.

Another problem with the use of subclassing for composite states is that entry/exit action methods then will be inherited by contained states, and as described above this is not the semantics of entry/exit actions of composite states according to UML (OMG, 2015). In our example, if the states CD and TV inherit the entry/exit actions of the enclosing state On, then changing back and forth between the states CD and TV (by the event mode) would imply that the display backlight would be turned on and off for each state change.

3. COMPOSITE AND EXTENSIBLE STATE MACHINE_PATTERN

3.1 Pattern name
Composite and Extensible State Machine

3.2 Problem
How can composite states and specialization of state machines be combined when programming state machines?

3.3 Context
Whenever the simple state design pattern is not enough, and there is a need for both composite states and specialization of state machines. Even in situations where only one of composition or specialization is needed, the pattern is useful as it supports further development and in particular history and entry/exit actions. The pattern assumes an object-oriented language or framework, with mechanisms like inner classes, method forwarding, and subclassing.

3.4 Forces
Subclassing is a powerful object-oriented mechanism, but should only be used for either composite states or specialization of state machines.

All object-oriented languages support a notion of subclassing, but they differ with respect to what other language features and specific language constructs are available.

State machines may later be extended into more complex ones, so the solution should be scalable without being unnecessarily complicated.

3.5 Solution
The solution is to use method forwarding for composite states and subclassing for specialization of state machines. A template state machine diagram containing both composite states and subclassing is shown in Figure 3. The original state machine SM1 contains a number of states, including A and B. The state machine SM2 is a specialization of SM1, where the composite state B' (consisting of a number of states including B1 and B2) is a specialization of B.
Figure 3 SM2 is a specialization of SM1, the composite state B' is a specialization of B

A state machine like the one in Figure 3 can be implemented as illustrated by the template class and object diagrams in Figure 4. In order to use a combination of method forwarding and subclassing for making extensible state machines with composite states, there is a need for a general class StateMachine, with a general class State as an inner class. The enclState association between instances of State is used to support composite states.

A specialized state machine (e.g. SM1) is defined by a subclass of the StateMachine, defining the special states for this machine (A and B) as subclasses of the inherited class State. Further specializations (SM2) are made by making subclasses of SM1 and further add new states and/or extend inherited states (e.g. B extended into B').

Figure 4 Composite and extensible state machine implemented using subclassing and method forwarding
Using method forwarding, an event method call to a state is forwarded to its enclosing (composite) state in case the event method is not defined specifically for the current state. Each sub state object will have a link (enclState) to its composite state object, as illustrated in the object diagram in the right part of Figure 4. The Top state root state is reached when event method calls are forwarded to the root (i.e. not handled in any of the other states). The composite state structure should be set up as part of the constructors for the state classes. Each constructor should get a reference to the enclosing state object as parameter.

**Example.** The MediaSwitch state machine from Figure 1 uses composite states, but not specialization. Applying the current pattern gives that MediaSwitch should be implemented as given in Figure 5.

![Object diagram](image)

**Figure 5** Class diagram and object diagram with method forwarding links for the MediaSwitch state machine

The way in which inherited state classes may be extended depends upon the programming language, see the following section on Implementation.

**Implementation.** The following describes how the combined pattern may be implemented in Java. Figure 6 defines the general classes of StateMachine and State. In addition, we have included the interface IState which is used as the type of the enclState link. For each state machine, a subinterface of IState should be created, defining the event methods for that state machine. In case the design pattern should be extended to a framework, then predefined code for states would be in the class State. The context object (the object that has a state machine) will then also implement IState and forward any event method call to the corresponding method of its StateMachine object which in turn will call the method on the current state object. In order not to generate new State objects for each next state, the constructor for the state machine should generate state objects and set the links to their enclosing state.

```java
interface IState {}

class StateMachine {
    IState cs;                        // current state
    void changeState(Class ns){}

class State implements IState {
    IState enclState;               // enclosing state
}
```

**Figure 6** StateMachine and State

When it comes to specialization of state machines, (Chin and Millstein, 2008) provides a detailed description of what is required to make a design pattern in Java, and show how it is possible, by means of subclassing, to add
new states and extend states with new states and new events. The following is a simplified description of this. A final combined design pattern using forwarding for composite states and subclassing for specialization of state machines will have to include all the details of (Chin and Millstein, 2008).

The idea behind (Chin and Millstein, 2008) is that states of a general state machine are extended in specialized state machines. Java does not provide extension of inner, inherited classes, so that has to be done in this way:

- For states that shall be extended, subclasses of these state classes are defined in the special StateMachine class.
- Instead of denoting state objects by references, state objects are referenced by ‘reference methods’ (much like factory methods), and these may then be overridden to reference state objects according to the subclasses.

Using IState,StateMachine and State from Figure 5, the generic state machine SM1 in Figure 4 can then be implemented as shown in Figure 7. For illustration purposes, it is assumed that the state machine has a transition from state A to state B with event a as seen in Figure 3. In order to keep it simple, we have not included the constructors of the state classes, and we have not specified what should be the behaviour of a (and other event methods) in case they are forwarded to the root TopState. Implementation of these methods will tell whether it is an error or simply a no-op to get such events in states where these events do not define any transition.

```java
interface ISM1 extends IState {
    public void a();
}
class SM1 extends StateMachine implements ISM1 {
    SM1() {
        // generate state objects stateTopState, stateA, stateB
    }
    public void a() {
        (ISM1) cS.a();
    }
}
class TopState extends State implements ISM1 {
    TopState() {
    }
    public void a() {
    }
    // referencing methods for A and B
    ISM1 stateA() { return stateA; }
    ISM1 stateB() { return stateB; }
}
class A extends State implements ISM1 {
    public void a() {
        changeState(stateB());
    }
}
class B extends State implements ISM1 {
    public void a() {
    }
}
```

Figure 7 Generic implementation of a state machine

Using the same principles as above for specialization, and using method forwarding for composition, the state machine SM2 in Figure 4 can be implemented as shown in Figure 8. Here, the state B has to be extended in order to become a composite state (with B1 and B2 as contained states). Java does not support extension of classes, so we define B’ as a subclass of the inherited B, and then override the corresponding referencing method for B to yield the an object according to B’.
Example. Following the implementation design for MediaSwitch given in Figure 5, this can then be implemented in Java as given in Figure 9.

The ‘...’ in the event methods represent the actions of the transition, followed by a specification of the next state. In case there is no method forwarding, then programmers of the event method simply use the `changeState` method, see e.g. `changeState(stateOn)` in the event method on in state Off. In case of method forwarding, programmers have to call the corresponding method on the enclosing state, see e.g. `(SwitchState)enclState.off()` in the event methods off in state CD and TV.

3.6 Rationale

While a subclassing solution to composite states creates the composite states by making the state class/subclass hierarchy, the method forwarding solution specifies the state structure by a structure of state objects. The benefit of using method forwarding in addition to subclassing is that it is a well-known mechanism; in addition, we do not have to invent a mechanism just for the purpose of composite states.
The above design pattern is based upon a more elaborate framework (Andresen et al., 2015). In order to support entry/exit actions and history, the design pattern above has to be combined with such a framework of predefined classes for StateMachine and the inner State. Entry/exit actions are in the framework defined as methods in the class State; these may then be overridden in specific states, and the framework will ensure that they are called in the right order when states are entered/exited. In order to support transition to history states, the framework ensures that each time a state is entered, the state is set as the shallow history of its immediate enclosing composite state. In order to support transition to deep history states, each time the current state changes, one will have to traverse the state hierarchy from the current state and up to the root state, and for all composite states on the path store current state as their deep history.

3.8 Related Patterns

According to the classification scheme of (Noble, 1998) our design pattern is an extension of the original state design pattern, in that it supports both composite states and specialization of state machines.

(Dyson and Anderson, 1998) present seven refinements/extensions of the original state design pattern. Our design pattern is also based upon the original state design pattern, so all of these seven refinements/extensions may be applied as well. Among the seven there is no extension for specialization of state machines.

In (Henney, 2003), states are not represented by objects according to state classes, but by methods, or in fact by references to methods. This requires the language to support references to methods, and the approach will have difficulties in supporting specialization of state machines.
The only approach in the survey (Adamczyk, 2003) that is similar to ours is the one called Subclassing State Machines (Sane and Cambell, 1995). It describes how to specialize a state machine, and it composes state machines, but it does not support hierarchical state machine by means of composite states. They have the notion of composite state, but that is rather a state that stems from a composed state machine and therefore is e.g. a pair of states from each of the composed state machines.

The Pattern Language of Statecharts (Jacoub and Ammar, 1998) is also similar to our approach in that it devise hierarchical statecharts by means of references, one from leaf states (state being part of another state) to its container states, and another (currentState) from a container state to the current state with the container. This last reference also facilitates History. However, specialization of state machines is not supported.

4. DISCUSSION

4.1 Language support

The implementation described above is based upon the existing language mechanisms of Java. However, although it works, it is cumbersome and error-prone to have to make subclasses of the states that shall be extended (in order to cope with new events or to be changed from a simple state to a composite state), and in addition override referencing methods correspondingly.

Extension of states means extension of state classes. A solution would therefore be to define the framework class State as a virtual class (Madsen and Møller-Pedersen, 1989), see Figure 10. Virtual classes are supported by a number of languages ((Madsen et al., 1993), (Ernst, 1999), (Aracic et al., 2006), (Bracha et al., 2010)), however in the following the idea is simply just sketched graphically. Composite states are still handled by method forwarding. A virtual class is just like a virtual method: it must be an inner class, and in a subclass of the enclosing class it may be given a new definition. While a virtual method may be overridden (that is completely redefined, except for its signature), a virtual class can only be extended, as if making a subclass of the virtual class. The reason that virtual classes can only be extended is obvious: it must be ensured that references typed by a virtual class can only denote objects with at least the properties of the virtual class.

![Figure 10 State as a virtual class in the framework](image-url)

A specific state machine, e.g. the Switch, is then defined as a subclass ofStateMachine, extending the virtual class State so that it implements the event methods for the switch (on and off), and then define the states of Switch as subclasses of the extended State class, see Figure 11. The new subclasses of State are defined to be virtual classes as well, so that further specializations may extend them. Further specializations may therefore also redefine event methods for the states. The extended virtual class State in Switch is still virtual (although extended), so a further specialization of Switch may extend State in order to add new event methods.

![Figure 11 A specialized StateMachine with extended State and specific states](image-url)
Figure 12 illustrates how the MediaSwitch is defined as a subclass of Switch. The class State is extended in order to implement the new event method mode, the states CD and TV are added as subclass of State, and On is extended in order to become a composite state. The fact that the state classes of a state machine are virtual classes implies that the construction of the state object hierarchy may be inherited and does not have to be made again for specialized state machines. As an example, the constructor for Switch in Figure 11 will have a statement that generates an On state object and sets the encloser to be an object of class SwitchState. The MediaSwitch state machine inherits this constructor, and as On has been extended, the inherited generation statement will now generate an object of the extended On. In this respect a virtual class works the same way as a virtual method: like a call of virtual method implies a call of the overridden method in case the call is made in the context of a subclass, generation of an object of a virtual class will imply generation of an object of the extended class.

As part of extending a virtual state class, it is possible to override inherited event methods. In principle an event method may be completely overridden, i.e. changing also the next state of the transition, and that is not desirable. A simple solution is to define the event methods as non-virtual (like final in Java) and then rather define for each event method a corresponding virtual action method that is called by the event method.

5. RELATED WORK

As described in the introduction, the original state design pattern does not cover composite states. Existing state machine APIs in various programming languages also support full state machines, but without any attempts to integrate the state machine mechanisms with the mechanisms of language.

Among the approaches that are integrated with existing language mechanisms, the Actor model (Hewitt, Bishop et al. 1973) was the first approach. Actors can change description (class) explicitly and thereby accepting a new set of messages. The Modes approach (Taivalsaari, 1993) also belongs to the well-integrated approaches, and it is directed towards supporting state-oriented programming in that an object does not have to change its class, only its virtual method dispatch pointer.

State-Oriented Programming (Sterkin 2008) is very similar to our approach. It recognizes that states have to be defined by objects that are linked to represent state hierarchies, but does not use method forwarding.

The Typestate-Oriented Programming ((Aldrich, Sunshine et al. 2009), (Sunshine, Naden et al. 2011)) supported by the Plaid language is a quite different approach. It is in line with Modes and with our approach in that state mechanisms are well integrated in the language, however, it only supports simple states. The reason is that the main objective is to define a corresponding type system that will make it possible to check that objects behave in accordance to the constraints specified by state types.

ACKNOWLEDGEMENTS

We would first like to thank our shepherd Stefan Sobernig for valuable feedback, both in terms of the shape of the paper and on its details. Secondly we would like to thank our group during the PLoP’16 for feedback on writing patterns the right way.
